# 9.7 Globally Convergent Methods for Nonlinear Systems of Equations

We have seen that Newton's method for solving nonlinear equations has an unfortunate tendency to wander off into the wild blue yonder if the initial guess is not sufficiently close to the root. A *global* method is one that converges to a solution from almost any starting point. In this section we will develop an algorithm that combines the rapid local convergence of Newton's method with a globally convergent strategy that will guarantee some progress towards the solution at each iteration. The algorithm is closely related to the quasi-Newton method of minimization which we will describe in §10.7.

Recall our discussion of §9.6: the Newton step for the set of equations

$$\mathbf{F}(\mathbf{x}) = 0 \tag{9.7.1}$$

is

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \delta \mathbf{x} \tag{9.7.2}$$

where

$$\delta \mathbf{x} = -\mathbf{J}^{-1} \cdot \mathbf{F} \tag{9.7.3}$$

Here **J** is the Jacobian matrix. How do we decide whether to accept the Newton step  $\delta \mathbf{x}$ ? A reasonable strategy is to require that the step decrease  $|\mathbf{F}|^2 = \mathbf{F} \cdot \mathbf{F}$ . This is the same requirement we would impose if we were trying to minimize

$$f = \frac{1}{2} \mathbf{F} \cdot \mathbf{F} \tag{9.7.4}$$

(The  $\frac{1}{2}$  is for later convenience.) Every solution to (9.7.1) minimizes (9.7.4), but there may be local minima of (9.7.4) that are not solutions to (9.7.1). Thus, as already mentioned, simply applying one of our minimum finding algorithms from Chapter 10 to (9.7.4) is *not* a good idea.

To develop a better strategy, note that the Newton step (9.7.3) is a *descent direction* for f:

$$\nabla f \cdot \delta \mathbf{x} = (\mathbf{F} \cdot \mathbf{J}) \cdot (-\mathbf{J}^{-1} \cdot \mathbf{F}) = -\mathbf{F} \cdot \mathbf{F} < 0$$
(9.7.5)

Thus our strategy is quite simple: We always first try the full Newton step, because once we are close enough to the solution we will get quadratic convergence. However, we check at each iteration that the proposed step reduces f. If not, we *backtrack* along the Newton direction until we have an acceptable step. Because the Newton step is a descent direction for f, we are guaranteed to find an acceptable step by backtracking. We will discuss the backtracking algorithm in more detail below.

Note that this method essentially minimizes f by taking Newton steps designed to bring **F** to zero. This is *not* equivalent to minimizing f directly by taking Newton steps designed to bring  $\nabla f$  to zero. While the method can still occasionally fail by landing on a local minimum of f, this is quite rare in practice. The routine newt below will warn you if this happens. The remedy is to try a new starting point. Permission is granted for internet users to make one paper copy for their own personal use. #### Line Searches and Backtracking

When we are not close enough to the minimum of f, taking the full Newton step  $\mathbf{p} = \delta \mathbf{x}$ need not decrease the function; we may move too far for the quadratic approximation to be valid. All we are guaranteed is that *initially* f decreases as we move in the Newton direction. So the goal is to move to a new point  $\mathbf{x}_{new}$  along the *direction* of the Newton step  $\mathbf{p}$ , but not necessarily all the way:

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \lambda \mathbf{p}, \qquad 0 < \lambda < 1 \tag{9.7.6}$$

The aim is to find  $\lambda$  so that  $f(\mathbf{x}_{old} + \lambda \mathbf{p})$  has decreased sufficiently. Until the early 1970s, standard practice was to choose  $\lambda$  so that  $\mathbf{x}_{new}$  exactly minimizes f in the direction  $\mathbf{p}$ . However, we now know that it is extremely wasteful of function evaluations to do so. A better strategy is as follows: Since  $\mathbf{p}$  is always the Newton direction in our algorithms, we first try  $\lambda = 1$ , the full Newton step. This will lead to quadratic convergence when  $\mathbf{x}$  is sufficiently close to the solution. However, if  $f(\mathbf{x}_{new})$  does not meet our acceptance criteria, we *backtrack* along the Newton direction, trying a smaller value of  $\lambda$ , until we find a suitable point. Since the Newton direction is a descent direction, we are guaranteed to decrease f for sufficiently small  $\lambda$ .

What should the criterion for accepting a step be? It is *not* sufficient to require merely that  $f(\mathbf{x}_{new}) < f(\mathbf{x}_{old})$ . This criterion can fail to converge to a minimum of f in one of two ways. First, it is possible to construct a sequence of steps satisfying this criterion with f decreasing too slowly relative to the step lengths. Second, one can have a sequence where the step lengths are too small relative to the initial rate of decrease of f. (For examples of such sequences, see [1], p. 117.)

A simple way to fix the first problem is to require the *average* rate of decrease of f to be at least some fraction  $\alpha$  of the *initial* rate of decrease  $\nabla f \cdot \mathbf{p}$ :

$$f(\mathbf{x}_{\text{new}}) \le f(\mathbf{x}_{\text{old}}) + \alpha \nabla f \cdot (\mathbf{x}_{\text{new}} - \mathbf{x}_{\text{old}})$$
(9.7.7)

Here the parameter  $\alpha$  satisfies  $0 < \alpha < 1$ . We can get away with quite small values of  $\alpha$ ;  $\alpha = 10^{-4}$  is a good choice.

The second problem can be fixed by requiring the rate of decrease of f at  $\mathbf{x}_{new}$  to be greater than some fraction  $\beta$  of the rate of decrease of f at  $\mathbf{x}_{old}$ . In practice, we will not need to impose this second constraint because our backtracking algorithm will have a built-in cutoff to avoid taking steps that are too small.

Here is the strategy for a practical backtracking routine: Define

$$g(\lambda) \equiv f(\mathbf{x}_{\text{old}} + \lambda \mathbf{p})$$
 (9.7.8)

so that

$$g'(\lambda) = \nabla f \cdot \mathbf{p} \tag{9.7.9}$$

If we need to backtrack, then we model g with the most current information we have and choose  $\lambda$  to minimize the model. We start with g(0) and g'(0) available. The first step is always the Newton step,  $\lambda = 1$ . If this step is not acceptable, we have available g(1) as well. We can therefore model  $g(\lambda)$  as a quadratic:

$$g(\lambda) \approx [g(1) - g(0) - g'(0)]\lambda^2 + g'(0)\lambda + g(0)$$
 (9.7.10)

Taking the derivative of this quadratic, we find that it is a minimum when

$$\lambda = -\frac{g'(0)}{2[g(1) - g(0) - g'(0)]}$$
(9.7.11)

Since the Newton step failed, we can show that  $\lambda \lesssim \frac{1}{2}$  for small  $\alpha$ . We need to guard against too small a value of  $\lambda$ , however. We set  $\lambda_{\min} = 0.1$ .

On second and subsequent backtracks, we model g as a cubic in  $\lambda$ , using the previous value  $g(\lambda_1)$  and the second most recent value  $g(\lambda_2)$ :

$$g(\lambda) = a\lambda^{3} + b\lambda^{2} + g'(0)\lambda + g(0)$$
(9.7.12)

Requiring this expression to give the correct values of g at  $\lambda_1$  and  $\lambda_2$  gives two equations that can be solved for the coefficients a and b:

$$\begin{bmatrix} a\\b \end{bmatrix} = \frac{1}{\lambda_1 - \lambda_2} \begin{bmatrix} 1/\lambda_1^2 & -1/\lambda_2^2\\ -\lambda_2/\lambda_1^2 & \lambda_1/\lambda_2^2 \end{bmatrix} \cdot \begin{bmatrix} g(\lambda_1) - g'(0)\lambda_1 - g(0)\\ g(\lambda_2) - g'(0)\lambda_2 - g(0) \end{bmatrix}$$
(9.7.13)

The minimum of the cubic (9.7.12) is at

$$\lambda = \frac{-b + \sqrt{b^2 - 3ag'(0)}}{3a} \tag{9.7.14}$$

We enforce that  $\lambda$  lie between  $\lambda_{max} = 0.5\lambda_1$  and  $\lambda_{min} = 0.1\lambda_1$ .

The routine has two additional features, a minimum step length alamin and a maximum step length stpmax. lnsrch will also be used in the quasi-Newton minimization routine dfpmin in the next section.

SUBROUTINE lnsrch(n,xold,fold,g,p,x,f,stpmax,check,func)
INTEGER n
LOGICAL check
REAL f,fold,stpmax,g(n),p(n),x(n),xold(n),func,ALF,TOLX
PARAMETER (ALF=1.e-4,TOLX=1.e-7)
EXTERNAL func

C USES func

Given an n-dimensional point xold(1:n), the value of the function and gradient there, fold and g(1:n), and a direction p(1:n), finds a new point x(1:n) along the direction p from xold where the function func has decreased "sufficiently." The new function value is returned in f. stpmax is an input quantity that limits the length of the steps so that you do not try to evaluate the function. The output quantity check is false on a normal exit. It is true when x is too close to xold. In a minimization algorithm, this usually signals convergence and can be ignored. However, in a zero-finding algorithm the calling program should check whether the convergence is spurious.

Parameters: ALF ensures sufficient decrease in function value; TOLX is the convergence criterion on  $\Delta x$ . INTEGER i

```

Here now is the globally convergent Newton routine newt that uses lnsrch. A feature of newt is that you need not supply the Jacobian matrix analytically; the routine will attempt to compute the necessary partial derivatives of **F** by finite differences in the routine fdjac. This routine uses some of the techniques described in  $\S5.7$  for computing numerical derivatives. Of course, you can always replace fdjac with a routine that calculates the Jacobian analytically if this is easy for you to do.

```
SUBROUTINE newt(x,n,check)

LOGICAL check

REAL x(n),fvec,TOLF,TOLMIN,TOLX,STPMX

PARAMETER (NP=40,MAXITS=200,TOLF=1.e-4,TOLMIN=1.e-6,TOLX=1.e-7,

STPMX=100.)

COMMON /newtv/ fvec(NP),nn Communicates with fmin.

SAVE /newtv/
```

C USES fdjac,fmin,lnsrch,lubksb,ludcmp

Given an initial guess x(1:n) for a root in n dimensions, find the root by a globally convergent Newton's method. The vector of functions to be zeroed, called fvec(1:n) in the routine below, is returned by a user-supplied subroutine that *must* be called funcv and have the declaration subroutine funcv(n, x, fvec). The output quantity check is false on a normal return and true if the routine has converged to a local minimum of the function fmin defined below. In this case try restarting from a different initial guess. Parameters: NP is the maximum expected value of n; MAXITS is the maximum number of iterations; TOLF sets the convergence criterion on function values; TOLMIN sets the criterion for deciding whether spurious convergence to a minimum of fmin has occurred; TOLX is the convergence criterion on  $\delta x$ ; STPMX is the scaled maximum step length allowed in line searches.

SUBROUTINE fdjac(n,x,fvec,np,df) INTEGER n,np,NMAX REAL df(np,np),fvec(n),x(n),EPS

С

C

PARAMETER (NMAX=40, EPS=1.e-4) USES funcv Computes forward-difference approximation to Jacobian. On input, x(1:n) is the point at which the Jacobian is to be evaluated, fvec(1:n) is the vector of function values at the point, and np is the physical dimension of the Jacobian array df(1:n,1:n) which is output. subroutine funcv(n,x,f) is a fixed-name, user-supplied routine that returns the vector of functions at  $\mathbf{x}$ . Parameters: NMAX is the maximum value of n; EPS is the approximate square root of the machine precision. INTEGER i,j REAL h,temp,f(NMAX) do 12 j=1,n temp=x(j) h=EPS\*abs(temp) if(h.eq.0.)h=EPS x(j)=temp+h Trick to reduce finite precision error. h=x(j)-temp call funcv(n,x,f) x(j)=temp Forward difference formula. do 11 i=1,n df(i,j)=(f(i)-fvec(i))/h enddo 11 enddo 12 return END FUNCTION fmin(x) INTEGER n.NP REAL fmin,x(\*),fvec PARAMETER (NP=40) COMMON /newtv/ fvec(NP),n SAVE /newtv/ USES funcv Returns  $f = \frac{1}{2} \mathbf{F} \cdot \mathbf{F}$  at x. subroutine funcv(n,x,f) is a fixed-name, user-supplied routine that returns the vector of functions at x. The common block newtv communicates the function values back to newt. INTEGER i REAL sum call funcv(n,x,fvec)

sum=0. do 11 i=1,n sum=sum+fvec(i)\*\*2 enddo 11 fmin=0.5\*sum return END

The routine newt assumes that typical values of all components of x and of F are of order unity, and it can fail if this assumption is badly violated. You should rescale the variables by their typical values before invoking newt if this problem occurs.

### Multidimensional Secant Methods: Broyden's Method

Newton's method as implemented above is quite powerful, but it still has several disadvantages. One drawback is that the Jacobian matrix is needed. In many problems analytic derivatives are unavailable. If function evaluation is expensive, then the cost of finite-difference determination of the Jacobian can be prohibitive.

Just as the quasi-Newton methods to be discussed in  $\S10.7$  provide cheap approximations for the Hessian matrix in minimization algorithms, there are quasi-Newton methods that provide cheap approximations to the Jacobian for zero finding. These methods are often called *secant methods*, since they reduce to the secant method ( $\S9.2$ ) in one dimension (see, e.g., [1]). The best of these methods still seems to be the first one introduced, *Broyden's method* [2].

Let us denote the approximate Jacobian by **B**. Then the *i*th quasi-Newton step  $\delta \mathbf{x}_i$  is the solution of

$$\mathbf{B}_i \cdot \delta \mathbf{x}_i = -\mathbf{F}_i \tag{9.7.15}$$

where  $\delta \mathbf{x}_i = \mathbf{x}_{i+1} - \mathbf{x}_i$  (cf. equation 9.7.3). The quasi-Newton or secant condition is that  $\mathbf{B}_{i+1}$  satisfy

$$\mathbf{B}_{i+1} \cdot \delta \mathbf{x}_i = \delta \mathbf{F}_i \tag{9.7.16}$$

where  $\delta \mathbf{F}_i = \mathbf{F}_{i+1} - \mathbf{F}_i$ . This is the generalization of the one-dimensional secant approximation to the derivative,  $\delta F / \delta x$ . However, equation (9.7.16) does not determine  $\mathbf{B}_{i+1}$  uniquely in more than one dimension.

Many different auxiliary conditions to pin down  $\mathbf{B}_{i+1}$  have been explored, but the best-performing algorithm in practice results from Broyden's formula. This formula is based on the idea of getting  $\mathbf{B}_{i+1}$  by making the least change to  $\mathbf{B}_i$  consistent with the secant equation (9.7.16). Broyden showed that the resulting formula is

$$\mathbf{B}_{i+1} = \mathbf{B}_i + \frac{(\delta \mathbf{F}_i - \mathbf{B}_i \cdot \delta \mathbf{x}_i) \otimes \delta \mathbf{x}_i}{\delta \mathbf{x}_i \cdot \delta \mathbf{x}_i}$$
(9.7.17)

You can easily check that  $\mathbf{B}_{i+1}$  satisfies (9.7.16).

Early implementations of Broyden's method used the Sherman-Morrison formula, equation (2.7.2), to invert equation (9.7.17) analytically,

$$\mathbf{B}_{i+1}^{-1} = \mathbf{B}_{i}^{-1} + \frac{(\delta \mathbf{x}_{i} - \mathbf{B}_{i}^{-1} \cdot \delta \mathbf{F}_{i}) \otimes \delta \mathbf{x}_{i} \cdot \mathbf{B}_{i}^{-1}}{\delta \mathbf{x}_{i} \cdot \mathbf{B}_{i}^{-1} \cdot \delta \mathbf{F}_{i}}$$
(9.7.18)

Then instead of solving equation (9.7.3) by e.g., LU decomposition, one determined

$$\delta \mathbf{x}_i = -\mathbf{B}_i^{-1} \cdot \mathbf{F}_i \tag{9.7.19}$$

by matrix multiplication in  $O(N^2)$  operations. The disadvantage of this method is that it cannot easily be embedded in a globally convergent strategy, for which the gradient of equation (9.7.4) requires **B**, not **B**<sup>-1</sup>,

$$\nabla(\frac{1}{2}\mathbf{F}\cdot\mathbf{F})\simeq\mathbf{B}^T\cdot\mathbf{F} \tag{9.7.20}$$

Accordingly, we implement the update formula in the form (9.7.17).

However, we can still preserve the  $O(N^2)$  solution of (9.7.3) by using QR decomposition (§2.10) instead of LU decomposition. The reason is that because of the special form of equation (9.7.17), the QR decomposition of  $\mathbf{B}_i$  can be updated into the QR decomposition of  $\mathbf{B}_{i+1}$  in  $O(N^2)$  operations (§2.10). All we need is an initial approximation  $\mathbf{B}_0$  to start the ball rolling. It is often acceptable to start simply with the identity matrix, and then allow O(N) updates to produce a reasonable approximation to the Jacobian. We prefer to spend the first N function evaluations on a finite-difference approximation to initialize  $\mathbf{B}$  via a call to fdjac.

Since **B** is not the exact Jacobian, we are not guaranteed that  $\delta \mathbf{x}$  is a descent direction for  $f = \frac{1}{2} \mathbf{F} \cdot \mathbf{F}$  (cf. equation 9.7.5). Thus the line search algorithm can fail to return a suitable step if **B** wanders far from the true Jacobian. In this case, we reinitialize **B** by another call to fd jac.

Like the secant method in one dimension, Broyden's method converges superlinearly once you get close enough to the root. Embedded in a global strategy, it is almost as robust World Wide Web sample page from NUMERICAL RECIPES IN FORTRAN 77: THE ART OF SCIENTIFIC COMPUTING (ISBN 0-521-43064-X) Copyright (C) 1988-1992 by Cambridge University Press. Programs Copyright (C) 1988-1992 by Numerical Recipes Software. Permission is granted for internet users to make one paper copy for their own personal use. as Newton's method, and often needs far fewer function evaluations to determine a zero. Note that the final value of **B** is *not* always close to the true Jacobian at the root, even when the method converges.

The routine broydn given below is very similar to newt in organization. The principal differences are the use of QR decomposition instead of LU, and the updating formula instead of directly determining the Jacobian. The remarks at the end of newt about scaling the variables apply equally to broydn.

```
SUBROUTINE broydn(x,n,check)
   INTEGER n,nn,NP,MAXITS
   REAL x(n), fvec, EPS, TOLF, TOLMIN, TOLX, STPMX
   LOGICAL check
   PARAMETER (NP=40,MAXITS=200,EPS=1.e-7,TOLF=1.e-4,TOLMIN=1.e-6,
         TOLX=EPS,STPMX=100.)
   COMMON /newtv/ fvec(NP),nn
                                               Communicates with fmin.
   USES fdjac,fmin,lnsrch,qrdcmp,qrupdt,rsolv
С
       Given an initial guess x(1:n) for a root in n dimensions, find the root by Broyden's method
       embedded in a globally convergent strategy. The vector of functions to be zeroed, called
       fvec(1:n) in the routine below, is returned by a user-supplied subroutine that must be
       called funcv and have the declaration subroutine funcv(n,x,fvec). The subroutine
       fdjac and the function fmin from newt are used. The output quantity check is false on a
       normal return and true if the routine has converged to a local minimum of the function fmin
       or if Broyden's can make no further progress. In this case try restarting from a different
       initial guess.
       Parameters: NP is the maximum expected value of n; MAXITS is the maximum number of
       iterations; EPS is close to the machine precision; TOLF sets the convergence criterion on
       function values; TOLMIN sets the criterion for deciding whether spurious convergence to a
       minimum of fmin has occurred; TOLX is the convergence criterion on \delta x; STPMX is the
       scaled maximum step length allowed in line searches.
   INTEGER i, its, j, k
    REAL den,f,fold,stpmax,sum,temp,test,c(NP),d(NP),fvcold(NP),
         g(NP),p(NP),qt(NP,NP),r(NP,NP),s(NP),t(NP),w(NP),
*

## More Advanced Implementations

One of the principal ways that the methods described so far can fail is if  $\mathbf{J}$  (in Newton's method) or  $\mathbf{B}$  in (Broyden's method) becomes singular or nearly singular, so that  $\delta \mathbf{x}$  cannot be determined. If you are lucky, this situation will not occur very often in practice. Methods developed so far to deal with this problem involve monitoring the condition number of  $\mathbf{J}$  and perturbing  $\mathbf{J}$  if singularity or near singularity is detected. This is most easily implemented if the QR decomposition is used instead of LU in Newton's method (see [1] for details). Our personal experience is that, while such an algorithm can solve problems where  $\mathbf{J}$  is exactly singular and the standard Newton's method fails, it is occasionally less robust on other problems where LU decomposition succeeds. Clearly implementation details involving roundoff, underflow, etc., are important here and the last word is yet to be written.

Our global strategies both for minimization and zero finding have been based on line searches. Other global algorithms, such as the *hook step* and *dogleg step* methods, are based instead on the *model-trust region* approach, which is related to the Levenberg-Marquardt algorithm for nonlinear least-squares ( $\S15.5$ ). While somewhat more complicated than line searches, these methods have a reputation for robustness even when starting far from the desired zero or minimum [1].
